Abstract Lotkaian informetrics is the framework most often used to study statistical distributions in the production and usage of information. Although Lotkaian distributions are traditionally used to characterize the Information Production Process (*IPP*), we have shown in a previous article that the *IPP* can successfully be studied using the effort function – the latter having been initially introduced to define the Exponential Informetric Process (*EIP*). These themes continue to be developed in this article, in which we present a necessary and sufficient condition for the existence of the *EIP*. Our current approach is similar to the one used to study *IPPs*. Inverse power and exponential distributions serve to illustrate the results obtained in the context of an *EIP*. Numerical examples are discussed.

Keywords Inverse power distribution, mathematical adjustment, effort function, entropy, exponential distribution

1. INTRODUCTION

Many statistical methods exist to model problems in humanities and social sciences, depending on the available quantitative information. One of the traditional models consists in adjusting different types of theoretical distributions to the empirical distributions that are being studied, as long as the empirical data allows it. The values of the parameters for the adjusted distributions then provide all the elements needed for a comparison. The adjustment method is implemented in three stages:

- choosing a theoretical model (exponential, inverse power, inverse power with cutoff, stretched exponential...)
- choosing a method to calculate the adjustment parameters (method of moments, linear least squares method, maximum likelihood estimation method...)
- choosing a statistical test to validate the theoretical model (the khi2 test, the Kolmogorov-Smirnov test...).

For the adjustment to be completely relevant, the theoretical model's parameters must be easy to interpret, allowing users to gain a better understanding of the observed phenomenon.

In the field of informetrics, we have come to observe many statistical regularities in the production and usage of information. These regularities have led researchers to work on models, using the steps described above. In practice, the characteristics of the production function don't vary much. The observed distributions are generally asymmetric, strongly decreasing with a long tail. The inverse power model, known as the lotkaian model (Egghe,

2005) is often selected as a first approximation to make adjustments. In continuous mode, the size frequency function is:

$$f(u) = \frac{C}{u^\alpha} \quad u \in [1, N], \quad \alpha > 1, C \in \mathbb{R}^+ \quad (1)$$

If we take the citations of scientific articles as an example (Albaran and Castillo, 2011), we notice that they are often adjusted by this distribution.

We also come across the exponential model, albeit less frequently. In continuous mode, the size frequency is:

$$f(u) = C \cdot \exp(-\alpha \cdot (u - 1)) \quad u \in [1, N], \quad \alpha > 0, C \in \mathbb{R}^+ \quad (2)$$

In both cases α and C are the parameters that need to be estimated. Parameter C is a simple normalizing coefficient and α characterizes the distribution. N is the maximal item per source density.

The method we have described in this introduction does, however, pose some difficulties, as two or more models can prove to be satisfactory. For example, the log-normal law (Petruszewycz, 1972) is very similar to the inverse power-distribution. Many adjustment methods exist (Clauset et al., 2009).

This paper offers a mathematical approach rather than a statistical one. We are therefore interested in the conditions linked to the choice of a model, when some of the parameters characterizing the production of the process are known. We use the concept of effort amount, or what is also known as entropy, as developed in the field of mathematical information theory (Weaver and Shannon, 1975)]. In this paper, we choose to use the method introduced by Leo Egghe in (Egghe, 2004) to find a necessary and sufficient condition for the existence of what has come to be known as the Exponential Informetric Process, abbreviated as *EIP*.

An *EIP* (see section 3), (Lafouge and Prime-Claverie, 2005) is the broader version of an *IPP* (see section 2), commonly used to represent informetric processes.

This article is composed of 4 parts and a conclusion:

- We review Egghe's results (Egghe, 2004) and their applications to exponential distributions (Lafouge, 2007) (see section 2).
- Certain aspects linked to *EIPs*, such as the amount of effort, are detailed (see section 3).
- The article's most significant result – the necessary and sufficient condition for the existence of an *EIP* – is presented in section 4.
- This necessary and sufficient condition is illustrated using 2 typical distributions: the exponential distribution (2) and the inverse power distribution (1). Numerical examples are used to apply these results (see section 5).
- A conclusion is presented.

2. A Reminder of Basic Theory Results

Figure 1: Information Production Process Diagram

Many of the phenomena studied in informetrics regarding the production and use of information can be represented by a triple process: the sources, the production and the items (see figure 1). This is known as the Information Production Process (IPP) (Egghe, 1990). It consists in having a set of sources and a set of items. S denotes the total number of sources and I , the total number of items. A production function quantifies the production of the items by the sources.. For an IPP, the number of sources S and the number of items I are calculated with the typical formulas:

$$\left\{ S = \int_1^N f(u)du \quad I = \int_1^N f(u)udu \quad \right\} \quad (3)$$

Where f is the IPP's size-frequency function and N is the maximal item per source density (in the discrete case, N designates the maximum number of items produced by a source). We use μ to represent the average number of items produced by a source:

$$\mu = \frac{I}{S} \quad (4)$$

If we consider that S and I are known $I > S > 0$ and that f is a known theoretical model, then creating a *mathematical source-item adjustment* consists in finding a necessary and sufficient condition for f to fulfil the condition (3). The term 'mathematical adjustment' used here designates a method introduced by Egghe within the field of informetrics to characterize inverse power distributions. It carries a different meaning from the adjustment method that is commonly used in statistics, as we mentioned in our introduction This problem was solved within the framework of Lotkaian informetrics (Egghe, 2004).

We can review the obtained results by distinguishing one case – where N , the maximum item per source density, is infinite – from the more realistic case that interests us – where N is finite, for both distributions (1) and (2).

(i) Exponential Distributions (Lafouge, 2007)

(a) N is infinite

The adjustment conditions (3) are met by (2) if and only if:

$$\alpha = \frac{S}{I-S} \quad (5)$$

$$C = \frac{S^2}{I-S} \quad (6)$$

α depends only on the ratio μ , unlike C which depends on S and μ .

(b) N is finite

The adjustment conditions (3) are met by (2), $N > 1$, if and only if:

$$\alpha < \frac{S}{I-S} \quad (7)$$

We therefore construct f by first calculating $N \neq 1$, obtained by solving a numerical equation with one unknown.

$$\frac{I}{S} \alpha - \frac{\exp(-\alpha(N-1))(-1-N.\alpha)+\alpha+1}{1-\exp(-\alpha(N-1))} \quad (8)$$

Where α is the parameter that verifies the inequality (7), with:

$$C = \frac{\alpha.S}{1-\exp(-\alpha.(N-1))} \quad (9)$$

We can find equations (5) and (6) by making N tend toward ∞ in (8) and (9).

(ii) Inverse Power distributions (Egghe, 2004)

(a) N is infinite

When $\alpha \leq 2$ I doesn't exist.

If α is greater than 2, then the adjustment conditions (3) are met if and only if:

$$\alpha = 1 + \frac{I}{I-S} = 2 + \frac{S}{I-S} \quad (10)$$

$$C = \frac{I.S}{I-S} \quad (11)$$

α depends only on the ratio μ , unlike C which depends on S and μ

The value 2 of α plays a pivotal role since the moment of order 1 can't exist if $\alpha \leq 2$.

(b) N is finite

Two cases exist:

- $N \geq 1$ always exists when $\alpha \leq 2$, thus (1) meets condition (3).

- if $\alpha > 2$, the previous conclusion is valid if and only if:

$$2 < \alpha < 1 + \frac{I}{I-S} = 2 + \frac{S}{I-S} \quad (12)$$

We then construct f by calculating N , which is obtained by solving a numerical equation with one unknown. Two cases are possible:

1. $\alpha \neq 2$

$$\frac{\alpha-1}{\frac{I}{S}(\alpha-2)} N^{2-\alpha} - N^{1-\alpha} + 1 - \frac{\alpha-1}{\frac{I}{S}(\alpha-2)} = 0 \quad (13)$$

Where α is a parameter verifying condition (12) with: $C = \frac{I.(2-\alpha)}{N^{2-\alpha}-1}$

2. $\alpha = 2$

$$\ln(N) + \frac{I}{S.N} - \frac{I}{S} = 0 \quad (14)$$

Where α is a parameter verifying condition (12) with: $C = \frac{1}{\ln(N)}$

(iii) **Discussion**

The calculation of α , when N is infinite – as seen in formulas (5) and (10) – is obtained through an adjustment done with the famous method of moments. This method can be used for an adjustment with an exponential distribution, but it is not suitable for an adjustment with an inverse power distribution, since the latter doesn't always have a moment of order 1.

The most interesting case is when N is finite. It should be noted that equations (8) and (13) – where N is the unknown and α is the parameter – depend only on the average number of items produced by a source. In the Inverse power distribution case, when N is finite or infinite, the $\alpha = 2$ case is a breaking point.

In these two examples, an existence theorem is used to solve the finite case – see section II.3.1.1, “the Theorem of Existence for the Size-frequency Function” in (Egghe, 2005).

This paper aims to provide additional elements to add to this important result. We will then recall the previous approach: the mathematical exponential (or power) adjustment of an *IPP*.

3. The Exponential Informetric Process and the Effort Amount

3.1 General Definition of an EIP

In this section, we assume that N (maximal item per source density) is infinite. We henceforth assume that each produced item requires a certain amount of effort. The difference between the *IPP* diagram (see figure 1) and the *EIP* diagram (see figure 2) is shown through the valuation of the arcs - for example, in order for item i_3 to be produced, source s_3 must have an effort quantified by value 3. The amount of effort needed to produce a source is generally unknown and difficult to quantify. We therefore introduce the effort function h , where $h(i)$ is designated as the average amount of effort from a source needed to produce i items, with $i = 1, 2, \dots$ (Lafouge and Prime-Claverie, 2005). As previously, we work in continuous mode and define an exponential informetric process where F denotes the average quantity of effort supplied by sources to produce all the items. This paper develops the theory by using the size-frequency function $e^{-\alpha h}$ where α is a positive number and h is an effort function. More precisely, we have a set of functions called *EF*:

$EF = \{h: [1, \infty] \rightarrow \mathbb{R}^+ \}$ strictly increasing and unbounded.

Figure 2: Diagram of an Information Production Process with an effort function: the EIP.

$h \in EF$ is called an admissible effort function if α exists as a real positive number verifying the condition:

$$\int_1^{\infty} \exp(-\alpha \cdot h(u)) \cdot h(u) du < \infty$$

We can recall results obtained in previous studies (Agouzal and Lafouge, 2008): with h being an admissible effort function, there exists a real $\sigma(h) \geq 0$, so that:

$$\forall \alpha > \sigma(h) \int_1^{\infty} \exp(-\alpha \cdot h(u)) \cdot h(u) du < \infty$$

We thus call the size frequency function f an 'exponential informetric process':

$$\{f(u) = C \cdot \exp(-\alpha \cdot h(u)) \mid u \in [1, \infty], C \in \mathbb{R}^+, h \in EF, \alpha > \sigma(h)\} \quad (15)$$

The corresponding probability density function v is:

$$v(u) = \frac{C \cdot \exp(-\alpha \cdot h(u))}{S}, u \in [1, \infty] \quad (16)$$

S is the number of sources:

$$S = \int_1^{\infty} C \cdot \exp(-\alpha \cdot h(u)) du$$

And F is the average amount of effort produced by the exponential informetric process:

$$F = \int_1^{\infty} C \cdot \exp(-\alpha \cdot h(u)) \cdot h(u) du \quad (17)$$

The amount of effort F is necessarily finite, since $\alpha > \sigma(h)$. It is entirely determined by the density function v , which governs the process.

The amount of produced items is written as:

$$I = \int_1^{\infty} C \cdot \exp(-\alpha \cdot h(u)) \cdot u du \quad (18)$$

The amount of items is not necessarily finite. There can therefore be an infinite amount of items produced by a finite amount of effort.

In the mathematical theory of information, the amount of effort and entropy are linked (Weaver and Shannon, 1975). When we calculate the $H(v)$ entropy of the v process, we can prove that:

$$H(v) = -\text{Ln}\left(\frac{C}{S}\right) + \alpha \frac{F}{S} \quad (19)$$

An exponential informetric process therefore has a finite entropy. We would have been able to define an admissible function with entropy.

m is defined as the average amount of effort produced by a source:

$$m = \frac{F}{S} \quad (20)$$

The average number of items produced by a source, when this number exists, is characteristic of an *IPP*. Similarly, the amount of effort needed to produce a source is characteristic of an *EIP*. Unlike for *IPPs*, this average exists, for *EIPs*, as soon as α is higher than 1, the latter being always verified for inverse power distributions.

3.2 Examples

3.2.1 Exponential Case

In this case, according to equation (2), the effort function is $h(u) = u - 1, \sigma(h) = 0$ and the amount of effort is:

$$F = I - S \quad (21)$$

This formula is valid whether N is finite or infinite.

3.2.2: Inverse Power Case

In this case, according to equation (1), the effort function is $h(u) = \text{Ln}(u), \sigma(h) = 1$. We now assume that $\alpha > 1$ The amount of effort is:

1. When N is infinite:

So, following the integration:

$$F = \int_1^\infty C \cdot \exp(-\alpha \cdot \text{Ln}(u)) du = \frac{C}{1-\alpha} \int_1^\infty \frac{d}{du}(u^{1-\alpha}) \cdot \text{Ln}(u) du \quad (22)$$

But, according to equation (16):

$$F = \frac{C}{(\alpha-1)^2} \quad (23)$$

$$C = S \cdot (\alpha - 1) \quad (24)$$

The amount of effort is therefore:

$$F = \frac{S}{(\alpha-1)} \quad (25)$$

Hence the result:

$$\alpha = 1 + \frac{S}{F} = 1 + \frac{1}{m} \quad (26)$$

The pivotal role of 2 as a value of α is shown through the following implications:

- $\alpha < 2$ implies that the amount of effort needed to produce all the items is higher than the number of sources,
- $\alpha = 2$ implies that the amount of effort needed to produce all items is equal to the number of sources,
- $\alpha > 2$ implies that the amount of effort needed to produce all items is lower than the number of sources.

According to (24) and (25), entropy (19) is written as:

$$H(v) = -\ln(\alpha - 1) + \frac{\alpha}{\alpha - 1} \quad (27)$$

We find the Lotka function's (Yablonsky, 1981) expected result – the decrease of entropy, according to α .

When $\alpha \geq 2$, according to (10), the amount of effort (25) is:

$$F = \frac{S}{I} \cdot (I - S) \quad (28)$$

The amount of effort is calculated according to I and S in the same way as for the exponential case. In this case, we have:

$$F < I - S$$

The amount of effort needed during the production of an *EIP* that is governed by an inverse power (with $\alpha > 2$) is therefore smaller than an *EIP* governed by an exponential. This characteristic fits with the properties of informetric inverse powers distributions, as in: the more items a source has, the higher the probability that it will produce a new item.

2. N is finite

Equation (22) is written as:

$$F = \frac{C}{1-\alpha} \cdot \ln(N) \cdot N^{1-\alpha} + \frac{S}{\alpha-1} \quad (29)$$

Application: calculating the amount of effort needed to produce words in a text.

To illustrate this notion, we use the typical case of a text's word production, well known in informetrics as Zipf's law. In this case, the number of S sources corresponds to the size of the lexicon. The total number of words in the text is the number of produced items, known as I . In (29), N designates the maximal frequency of a word in a text and is generally very high (often consisting of grammatical words such as "the" in the English language). Furthermore, we know that the distribution (frequency rank) of words in a text obeys Zipf's law:

$$g(r) = \frac{k}{r^\beta} \quad r \in [1, N], \quad \beta > 0, k \in \mathbb{R}^+$$

α and β are linked by the following well-known relation (see, for example, II. 2.2.1 in (Egghe, 2005)):

$$\beta = \frac{1}{\alpha-1}$$

if N tends towards infinity and If it obeys the Zipf law, then, according to (29), the amount of effort needed to produce a text is:

$$F \approx \beta \cdot S$$

In the ideal case where $\beta = 1$, the amount of effort is equal to the number of sources, i.e., to the size of the lexicon. β is generally slightly higher than 1; the effort needed to produce a text is therefore generally slightly higher than the lexicon's size.

As to avoid any possible confusion, we must clarify certain points linked to the effort function when discussing this application to the production of words in a text.

Discussion on the Effort Function

The effort function supposes that each used (or produced) item has a certain "cost". In his statistic theory of language (*Mandelbrot*, 1953), Mandelbrot introduced a cost function. Although he doesn't mention effort functions directly, the intention remains the same:

$h(r) = \frac{\ln(r)}{\ln(V)}$ (a) where V is the amount of different characters in the text and r is the word's rank (words are ranked by decreasing frequency). This function is based on the following hypothesis: the longer a word is, the higher the cost to produce it is.

This effort function has the following characteristics:

- As the number of different characters is reduced, the number of characters in words increases, and, according to (a), the amount of effort needed to produce them increases.
- The higher the rank is, the more words tend to have a large amount of characters and the rarer they are. According to (a), more effort amount is needed to produce them as the rank increases. Knowing the entropy H and the amount of effort F , Mandelbrot then calculated the probability $p(r)$ of a word by minimizing the average cost of information, $F = \frac{F}{H}$ (see for example the proof in (Mitzenmacher 2003)).

In this case, the effort function depends on the ranking of the frequency of words and it contributes to prove Zipf's law. An inefficient solution would have been to say that the cost of producing a word was proportional to the logarithm of a word's length.

An effort function partly defines an EIP . The result in section 4 legitimizes this introduction.

4. The Necessary and Sufficient Condition for the Existence of an Exponential Informetric Process

The exponential informetric process is defined by 4 parameters:

- $S > 0$ as the number of sources,
- $F > 0$ as the amount of effort needed to produce the process,
- h as the effort function that characterizes the process,

- $N > 1$, as the maximum item per source density.

We are looking for a necessary and sufficient condition, so that $C > 0$ and $\alpha > 0$ can exist as:

$$\left\{ S = \int_1^N C \cdot \exp(-\alpha \cdot h(u)) du \quad F = \int_1^N C \cdot \exp(-\alpha \cdot h(u)) \cdot h(u) du \right\} \quad (30)$$

Equations (30) play the same role as equations (3) in section 2. This is why we can talk about a generalisation.

Unlike section 2, N is a parameter that is supposedly known and that characterizes the process. It measures what is often referred to as the long tail of inverse power distributions. Here, the amount of effort F is what's supposedly known, whereas the number of produced items, I , is not. At first glance, the posed problem seems unrealistic since F , unlike I , is not observable. However, studying the existence of an *EIP* remains interesting since it allows us to add to the previous results and to develop the notion of the amount of effort needed to produce a process, itself governed by an exponential or power-law distribution.

Comment

Since the effort function h is a strictly increasing positive function, with $\alpha > 0$, this implies that $C \cdot \exp(-h(u))$ is a decreasing distribution. At first, we do not need to consider h as being admissible.

1. N is finite

With m to solve problem, (30) equates to finding a necessary and sufficient condition where $\alpha > 0$ exist and solves the following equation:

$$m = \frac{\int_1^N \exp(-\alpha \cdot h(u)) \cdot h(u) du}{\int_1^N \exp(-\alpha \cdot h(u)) du} \quad (31)$$

Equations (30) are indeed equivalent to:

$$\frac{\int_1^N \exp(-\alpha \cdot h(u)) \cdot h(u) du}{F} = \frac{\int_1^N \exp(-\alpha \cdot h(u)) du}{S} = \frac{1}{C}$$

Let $N > 1$, for $\alpha > 0$ we define function E_N as:

$$E_N(\alpha) = \int_1^N (h(u) - m) \cdot \exp(-\alpha \cdot (h(u) - m)) du \quad (32)$$

Solving equation (31) means finding $\alpha > 0$ so that $E_N(\alpha) = 0$:

$$E_N(\alpha) = 0 \Leftrightarrow \int_1^N (h(u) - m) \cdot \exp(-\alpha(h(u))) du = 0 \Leftrightarrow m = \frac{\int_1^N \exp(-\alpha \cdot h(u)) h(u) du}{\int_1^N \exp(-\alpha \cdot h(u)) du}$$

To conclude, α is the solution of equation (33), which depends on N , h and $m = \frac{F}{S}$:

$$E_N(\alpha) = 0 \Leftrightarrow \int_1^N (h(u) - m) \cdot \exp(-\alpha \cdot (h(u))) du - m \int_1^N \exp(-\alpha \cdot h(u)) du = 0 \quad (33)$$

Lemma 4.1 We have the following results : $h(1) < m < h(N)$ and E_N strictly decreases.

Proof

The Equality of (31) and the fact that h strictly increases allows us to write:

$$\frac{\int_1^N \exp(-\alpha \cdot h(u)h(1))du}{\int_1^N \exp(-\alpha \cdot h(u))du} < \frac{\int_1^N \exp(-\alpha \cdot h(u)h(u))du}{\int_1^N \exp(-\alpha \cdot h(u))du} < \frac{\int_1^N \exp(-\alpha \cdot h(u)h(N))du}{\int_1^N \exp(-\alpha \cdot h(u))du}$$

Thus, when simplifying:

$$h(1) < m < h(N)$$

The calculation of the derivative is:

$$\frac{dE_N}{d\alpha} = - \int_1^N (h(u) - m)^2 \cdot \exp(-\alpha \cdot (h(u) - m)) du$$

therefore, the E_N function is strictly decreasing.

This result highlights the fact that the average amount of effort needed to produce a source falls between the effort function's minimum and maximum. We shall now demonstrate the main result of this article. For the adjustment problem (30) to have a solution – *i.e.* α existing as the unique solution to the equation $E_N(\alpha) = 0$ – we must give a necessary and sufficient condition, linking the effort function h , the average effort amount m and the maximal item per source density, N .

Theorem 4.1 *For any $N > 1$, then there exists $\alpha > 0$ as unique solution so as to have $E_N(\alpha) = 0$, if and only if:*

$$m = \frac{F}{S} \in \left[h(1), \frac{\int_1^N h(u)du}{N-1} \right]$$

Proof

(i) Necessary Condition

According to the 4.2 lemma, E_N is a strictly decreasing function, so $\alpha > 0$ implies that:

$$0 = E_N(\alpha) < E_N(0) = \int_1^N (h(u) - m)du$$

Then:

$$h(1) < m < \frac{\int_1^N h(u)du}{N-1}$$

(ii) Sufficient Condition

The inequality of the 4.1 lemma and the intermediate value theorem implies that there exist $y \in [1, N]$ (unique solution, since h is strictly increasing) so that $m = h(y)$; when $u < y$, then $h(u) - m < 0$ and $(u) - m > 0$ when $u > y$, then:

$$E_N(\alpha) = \int_1^y (h(u) - m) \cdot \exp(-\alpha \cdot (h(u) - m))du + \int_y^N (h(u) - m) \cdot \exp(-\alpha \cdot (h(u) - m))du$$

so we can write: $\lim_{\alpha \rightarrow \infty} E_N(\alpha) = -\infty$.

Since E_N is strictly decreasing and $E_N(0) = \int_1^N (h(u) - m) > 0$ we can therefore conclude that $\alpha > 0$, with $E_N(\alpha) = 0$ as the unique solution

2. N is infinite

Although we aren't covering this case as a whole, two comments can be made.

First, when N is infinite, we must assume that the effort function h is admissible for F and m to be finite. An important property then completes the theorem.

Lemma 4.2 *If N tends towards infinity, then the function $g(N) = \frac{\int_1^N h(u)du}{N-1}$ tends towards infinity and is an increasing function.*

Proof

Since h isn't bounded, $\forall M > 0 \exists N$ so that $\forall u > N, h(u) > M$ then

$$\int_1^N h(u)du > (N-1)M$$

therefore

$$\frac{\int_1^N h(u)du}{N-1} > M$$

therefore g is not bounded.

The calculation of the derivative

$$\frac{dg(N)}{dN} = \frac{h(N) \cdot (N-1) - \int_1^N h(u)du}{(N-1)^2}$$

is positive, therefore g is increasing.

Discussion Before working on examples, we must think about the significance of such a result. First of all, we notice that, in the same way as for an *IPP*, the normalizing factor C doesn't play a part in this problem. It is entirely determined by α .

Lemma 4.2 allows us to precise the results of theorem 4.1. Supposing that we are in a stable process in which the number of sources is mostly fixed, the amount of effort increases slightly. Let's suppose that the necessary condition for the existence of an *EIP* is verified. Then, if N – the maximum number of items a source can produce – increases over time, then the condition of existence is always verified.

Let's take, as an example, the case where a relatively long text is produced. Let's suppose that the text is lengthened over time by its author. We can suppose that the size of the lexicon doesn't change very much. If the amount of effort increases slightly, the condition of theorem 4.1 remains true because of the fact that a word's maximal frequency, generally a grammatical word, becomes very high.

5. Examples of Processes

This theorem is now applied to the two types of distributions seen above in the context of *IPPs*.

5.1 Exponential Process

We shall call this method as follows: the mathematical exponential adjustment of an *EIP*.

1. N is finite

$F = I - S$ and the effort function is $h(u) = u - 1$. According to theorem 4.1, for any $N > 1$, and $m = \frac{F}{S} \in \left]0, \frac{N-1}{2}\right[$ (34)

α exists as unique solution to (33) :

$$\int_1^N u \cdot \exp(-\alpha \cdot (u - 1)) du - (1 + m) \int_1^N \exp(-\alpha \cdot (u - 1)) du = 0$$

According to (21), we have $m + 1 = \frac{I}{S}$

Following calculations, we then find, the same equation (8) as for the mathematical exponential adjustment of an *IPP*. Hence (30) implies that:

$$C = \frac{S \cdot \alpha}{1 - \exp(-(N-1) \cdot \alpha)}$$

Remarks

Equations for *IPPs* and *EIPs* are identical, but the solved problems are different. If we call this equation Fe , it depends on three values, α , m and N , which all play different roles in each equation. If we call the unknown x , then:

- In the case of an *IPP*, we find a necessary and sufficient condition for the equation $Fe(x, \alpha, m) = 0$ (here, $x = N$) to have a unique solution:

$$\alpha < \frac{1}{m}$$

- In the case of an *EIP*, we find a necessary and sufficient condition for the equation $Fe(N, x, m) = 0$ (here $x = \alpha$) to have a unique solution :

$$m < \frac{N - 1}{2}$$

We therefore proved the following result. Where $N > 1, I > S > 0$, a necessary and sufficient condition for $\alpha > 0$ and $C > 0$ to exist, verifying :

$$\left\{ S = \int_1^N C \cdot \exp(\alpha \cdot (u - 1)) du \quad I = \int_1^N C \cdot \exp(\alpha \cdot (u - 1)) (u - 1) du \right\} \quad (36)$$

is

$$\left\{ \alpha < \frac{S}{I-S} \quad \frac{I-S}{S} < \frac{N-1}{2} \right\} \quad (37)$$

We can illustrate this result with a numerical example.

2. Numerical example N°1

- The mathematical exponential adjustment of an *EIP*

Let $S = 5,000$ $F = 15,000$ and $N = 10$, then $I = 20,000$ and $m = 3$, we have equation (8) that takes the form of (38) (replacing α by x):

$$4x - \frac{\exp(-9x)(-1-10x)+1+x}{1-\exp(-9x)} \quad (38)$$

Which can be solved (since (34) is true) by using the MAPPLE 17 software, for e.g. we find $x \approx 0.239 = \alpha$ (35) implies that $C \approx 1,352$. To conclude, the exponential distribution is:

$$f(u) \approx 1,352. \exp(-0.239. (u - 1)) \quad u \in [1,10] \quad (39)$$

The result is coherent since the condition (7) of the mathematical exponential adjustment of an *IPP* is verified:

$$0.239 = \alpha < \frac{S}{I-S} = \frac{1}{m} = 0.33$$

- The mathematical exponential adjustment of an *IPP*

We use the same values as the previous example.

Let $S = 5,000$, $I = 20,000$ and $\alpha = 0.239$ then equation (8) takes the form of (40) (replacing N by x):

$$0.956 - \frac{(\exp(-0.239x+0.239))(-0.239x-1)+1.239}{1-\exp(-0.239x+0.239)} = 0 \quad (40)$$

Which can be solved (since (7) is true) by using the MAPPLE 17 software, for e.g. we find the expected result, which is $x \approx 10 = N$.

The result is coherent since the condition (34) of the mathematical exponential adjustment of an *EIP* is verified:

$$m = \frac{I-S}{S} = 3 < \frac{N-1}{2} = 4.5$$

3. N is infinite

If N tends towards infinity, then the equation is written as:

$$\frac{I}{S} \cdot \alpha - \alpha - 1 = 0$$

With the value of α being:

$$\alpha = \frac{1}{m} = \frac{S}{F} = \frac{S}{I-S} \quad (41)$$

We also have: $C = \frac{S^2}{I-S}$

We obtain the same result (see 5 and 6) as for the mathematical exponential adjustment of an *IPP*. This result was expected since the effort function in the exponential model is the identity function. The mathematical exponential adjustment of an *IPP* and the mathematical exponential adjustment of an *EIP* are identical.

Discussion Conditions (37) for the existence of an *IPP* that is governed by an exponential process are complete. For the exponential case, the amount of effort does not need to be known. All that needs to be known are the 3 essential characteristics of a distribution. The inverse power case is very different, as we are about to see.

5.2 Inverse Power Process

We shall call this method as follows: the mathematical inverse power adjustment of an EIP.

1. N is finite

The effort function is $\log u$. According to theorem 4.1, for any $N > 1$, and

$$m = \frac{F}{S} \in \left] 0, \frac{N \cdot \text{Ln}(N) - N + 1}{N - 1} \right[\quad (42)$$

There exists α , solution of (33):

$$\int_1^N \frac{\ln(u)}{u^\alpha} du - m \int_1^N \frac{1}{u^\alpha} du = 0$$

Therefore the equation to be solved is:

$$\frac{1}{1-\alpha} \int_1^N \frac{d(u^{1-\alpha})}{du} \cdot \ln(u) du - m \cdot \int_1^N u^{-\alpha} du = 0$$

Following calculations:

$$\frac{1}{1-\alpha} \text{Ln}(N) \cdot N^{1-\alpha} + (1 - N^{1-\alpha}) \left(\frac{m}{1-\alpha} + \frac{1}{(1-\alpha)^2} \right) = 0 \quad (43)$$

We also have, according to (30), the normalizing coefficient:

$$C = \frac{S \cdot (\alpha - 1)}{1 - N^{1-\alpha}} \quad (44)$$

2. Numerical example N°2

Let $S = 10,000$, $F = 6,000$ and $N = 10$; we have and $m = \frac{3}{5}$ and:

$$\frac{N \cdot \text{Ln}(N) - N + 1}{N - 1} = 1.5584$$

Equation (43) takes the following form (replacing α by x):

$$\frac{\text{Ln}(10) \cdot 10^{1-x}}{1-x} + (1 - 10^{1-x}) \cdot \left(\frac{0.6}{1-x} + \frac{1}{(1-x)^2} \right) = 0 \quad (45)$$

Since condition (42) is verified, this equation can be solved by using the MAPPLE 17 software, for e.g. we find $x \approx 2.47 = \alpha$. (44) implies that $C \approx 15,215$. To conclude, the power distribution is:

$$f(u) \approx 15,215 \cdot \frac{1}{u^{2.47}} \quad u \in [1, 10] \quad (46)$$

Numerical example N°3:

Let $S=5,000$, $F=7,000$ and $N=50$ we have $m=1.4$

$$\frac{N \cdot \ln(N) - N + 1}{N - 1} = 2.991$$

Equation (43) takes the following form (replacing α with x):

$$\frac{\ln(50) \cdot 50^{1-x}}{1-x} - (1 - 50^{1-x}) \cdot \left(\frac{1.4}{1-x} + \frac{1}{(1-x)^2} \right) = 0 \quad (47)$$

Since condition (42) is verified, this equation can be solved by using the MAPPLE 17 software, for e.g. we find $x \approx 1.46 = \alpha$. (44) implies that $C \approx 2,679$. To conclude, the power distribution is:

$$f(u) \approx \frac{2,679}{u^{1.46}} \quad u \in [1, 50] \quad (48)$$

4. N is infinite

If N tends towards infinity, then (43) is written as follows:

$$\frac{m}{1-\alpha} + \frac{1}{(1-\alpha)^2} = 0$$

With the value of α being:

$$\alpha = 1 + \frac{1}{m} = 1 + \frac{S}{F} \quad (49)$$

We find the expected result (see (26)) for the value of α . Furthermore, we deduce, based on (30), that:

$$C = S \cdot (\alpha - 1)$$

If $\alpha > 2$, then, according to (28), the equation (49) is written as follows:

$$\alpha = 1 + \frac{I}{I - S}$$

and

$$C = \frac{I \cdot S}{I - S}$$

i.e., the same result (see (10) and (11)) as for a mathematical inverse power distribution adjustment.

Discussion

In the case where N is infinite, we demonstrated the formula $\alpha = 1 + \frac{S}{F}$. This formula is true, whatever α 's value. The more the effort amount F decreases (or, the more entropy decreases), the more α increases. This means that the gap widens between a large number of sources that produce little and a small number of sources that produce a lot. Unlike in the case of an *(IPP)*, the value $\alpha=2$ is not a breaking point.

In the two numerical examples that were considered, when we compare the value of α , solution to the equation, it is roughly equal to $1 + \frac{S}{F}$

Example 2: exact calculation of α , 2.47, rough formula $\alpha \approx 2.67$

Example 3: exact calculation of α , 1.46, rough formula $\alpha \approx 1.7$

We can compare the necessary and sufficient conditions for the existence of an exponential process and of an inverse power process. For $N > 1$, the inequality is as follows:

$$\frac{N \cdot \ln(N) - N + 1}{N - 1} \leq \frac{N - 1}{2}$$

This inequality implies that if the mathematical power adjustment of an *EIP* is verified, then the same applies for a mathematical exponential adjustment. This result concurs with the mathematical adjustment of an *IPP* (see theorem 5 (Lafouge, 2007)).

If N is infinite, it is worth making a parallel between the coefficient α of the exponential (41) and of the inverse power (49).

$$\alpha = \frac{S}{F} \quad \alpha = 1 + \frac{S}{F}$$

This analogy allows us to better understand the role that the amount of effort plays in exponential and inverse power distributions.

Before concluding, it is important to clarify certain points – as we did for the effort function – so as to get more insight into the contributions and limits of this research.

Discussion: Limits and Contributions

The numerical examples used in this article weren't drawn from real situations. It is currently difficult for us to present such real results. The crucial problem lies in knowing the amount of effort – which is unknown and tied to the effort function, itself also unknown, as was shown above. We would need to perform calculations in a real life setting and choose a realistic value for F . We could then compare it with results obtained using the classic Lotkaian case.

The main contribution in creating an EIP lies in the fact that the EIP highlights the connection – though already known – between the amount of effort (or entropy (see (19)) as understood by Shannon) and informetric distributions. Lotkaian distributions serve to explain many statistical regularities. It therefore seems important to draw attention to two points:

- the role of the logarithm effort function. In a previous article (lafouge T and Smolczewska 2006), we showed that, if h is an effort function – positive, strictly increasing and unbounded – that verifies the relation

$$\lim_{x \rightarrow \infty} \frac{h(x)}{\ln(x)} = \alpha \quad \alpha > 1$$

then h is admissible and the amount of effort is finite. Unfortunately, such a condition is not necessary.

- We also want to highlight the pivotal point of $\alpha = 2$, since it corresponds to the case where the amount of effort is equal to the number of sources.

6. Conclusion

Both models are compared: the mathematical adjustment of an *IPP* initiated by Egghe, and the mathematical adjustment of an *EIP*, presented in this article. This is relevant only if the distribution is of the power or exponential type.

When N is infinite, the mathematical exponential adjustments of an *IPP* and of an *EIP* is identical.

When N is infinite and $\alpha > 2$, the mathematical power adjustment of an *IPP* and of an *EIP* are identical.

Results differ in a realistic case, when N is finite. In the exponential case, the mathematical adjustment of an *EIP* completes the result previously found for an *IPP*. This is due to the fact that the effort function is the identity, therefore $F = I - S$ whatever the value of N . In the power case, the value $\alpha = 2$ is not a breaking point for an *EIP*, whereas it is for an *IPP*. It would be interesting to study other effort functions (Lafouge and Smolczewska, 2006) in order to expand on the notion of *EIP* adjustments.
